Kevin L. Anderson, Ph.D., Van Andel Creation Research Center, Chino Valley, AZ 86323

Abstract

Much research has been done on the *ebg* operon of the bacterium *Escherichia coli* over the last 30 years. Although the function of the *ebg* operon is still unknown, it has been observed that specific mutations within this operon enable the bacterium to metabolize lactose sufficiently to allow growth. Interestingly, this growth occurs in a *lacZ*⁻ genotype (gene for β-galactosidase in the *lac* operon). Thus, this gene has been referred to as an "evolved β-galactosidase," and has been widely accepted as an example of "evolution in action." Under these cultivation conditions, the *ebg* operon appears to harbor adaptive mutations. Mutations (at codons 92 and 977) in the *ebgA* gene (which codes for *ebg* β-galactosidase) occur consistently when an *E. coli lacZ*⁻ population undergoes carbon starvation in the presence of lactose. These are the only mutations observed in the *ebgA* gene and these particular mutations are not found when the bacteria are subjected to different adverse environmental conditions. Mutations are also found in other genes suggesting a mechanism which has effects on the entire genome. Several models have been proposed to explain this phenomenon.

Hall's work needs critical evaluation. Mutations in the *Ebg* system are clearly not an example of evolution but mutation and natural selection allowing for adaptation to the environment. Several possibilities for the function of the *Ebg* system are suggested. In addition, there is an assessment of the likelihood of these mutations in the *ebg* operon occurring in a natural setting. An implication of this research is an understanding that adaptive mutation makes "limited" changes which severely restrict its use as a mechanism for evolution.

Adaptive mutations can readily fit within a creation model where adaptive mechanisms are a designed feature of bacteria. Further understanding of these mutations in the *ebg* operon may help the development of a creation model for adaptation of bacterial populations in response to the adverse environmental conditions in a post-Fall, post-Flood world.

Keywords

Mutation, Adaptive, *ebg*, Hall, *lac*, Hypermutable, Evolution, Natural selection

Introduction

For over 150 years the mantra of evolutionists has been that random changes/mutations directed by natural selection is the driving force of evolution (common descent of all life). Although biblical creationists do not deny that these forces occur, they do not equate them with evolutionary transformations necessary for common descent. Edward Blyth, a creationist, was one of the first individuals to formulate the idea of natural selection. Mutation and natural selection in populations of bacteria, animals, and humans are readily observable. Mutations can be classified as deleterious, neutral or beneficial with beneficial being by far the smallest category. Beneficial mutations typically lead to relatively small changes that give an organism an advantage in a

specific environment. For example, in a population of beach mice (*Peromyscus polionotus*) a mutation was found in the *Mc1r* gene that alters the coat color such that it is lighter, similar to the color of the sand where the mice live (Hoekstra, Hirschmann, Bunday, Insel, & Crossland, 2006). In the beach environment, there is a selective advantage for this lighter coat color because it may allow better camouflage protection from predators. However, the benefit of this mutation is extremely limited in its scope. Should the environment change or the mouse population relocate, this particular allele of the *Mc1r* gene might become disadvantageous, making the value of this beneficial mutation very context-dependent. Also, the light fur coloring resulted from a mutation that decreased pigment production. Hence, it may have

provided a beneficial phenotype, but the mutation was genetically deleterious.

Another example of beneficial mutations is antibiotic resistance in bacteria. This has become a popular example of “evolution in action.” Antibiotic resistance mutations encompass a wide variety of mutations that alter targeted bacterial proteins. For a comprehensive review of these see Anderson (2005). Although the mutant bacteria gain a survival advantage in the presence of antibiotics, they often do not compete as well with wild-type bacteria in an environment without antibiotics. In addition, resistance may provide a beneficial phenotype, but it usually results from mutations that eliminate or reduce specific genetic function, such as gene regulation or expression (Anderson, 2005). So again, this type of change is beneficial only in very specific environments.

Mutations are commonly thought to be random changes in the DNA that may or may not be beneficial to an organism in its environment. However, studies have indicated that adverse environmental conditions may initiate mechanisms in bacteria that lead to mutations which specifically allow the bacteria to survive and grow in the given environment (see, for example, Bjedov et al., 2003; Hall, 1991; Hall & Hartl, 1974; Torkelson, Harris, Lombardo, Nagendran, Thulin, & Rosenberg, 1997). Initially these were termed “directed” mutations but are now more appropriately called adaptive mutations. Barry Hall, professor emeritus of the University of Rochester, New York, has done extensive work in the field of adaptive mutations. His work on the *ebg* operon in *Escherichia coli* has been offered to refute biochemist Michael Behe’s (1998) challenge that some systems have a complex interrelationship with no possible evolutionary intermediate stages or transitions of development (that is, irreducible complexity). In his book, *Finding Darwin’s God*, Kenneth Miller (1999) believes,

The most direct way to do this [show irreducibly complex systems can evolve] would be with a true acid test—by using the tools of molecular genetics to wipe out an existing multipart system and then see if evolution can come to the rescue with a system to replace it. (p. 145).

Miller is convinced that Hall’s work with the *ebg* operon passes the “true acid test” with flying colors, “No doubt about it—the evolution of biochemical systems, even complex multipart ones, is explicable in terms of evolution.” (p. 147). Behe and Miller have had several internet exchanges devoted to this topic (Behe, 2000; Miller, n.d.). While mutations can help bacteria adapt to their environment, such mutations should not be equated with evolution.

There are two reasons why the concept of adaptive

mutations would appear to be problematic for neo-Darwinism proponents. First, although the mutations themselves are random (at least according to current models), the mechanism for generating mutations is specifically responding to environmental clues. In this setting, mutation and natural selection become goal-oriented. While this is expected for an adaptation mechanism, evolutionary mechanisms are specifically identified as goal-less. A second reason is that the mechanisms of adaptive mutations may reveal there are limits to the genetic change possible by mutations of genes in organisms. With the *ebgA* gene, only 2 mutations in the gene were ever observed after countless *in vivo* studies. On-the-other-hand, *in vitro* studies have shown a wide variety of mutations that can make the enzyme more efficient in hydrolyzing a substrate (Mastrobattista, Taly, Chanudet, Treacy, Kelly, & Griffiths, 2005).

It may be especially important for bacteria to genetically possess a “rigid flexibility.” Such flexibility would allow bacteria the necessary genetic versatility to adapt to exposure to ever-changing environments (Anderson, 2003). Yet, the rigidity of possible changes would limit the bacteria to remain within its created baramin (Frair, 2000). This fits with observable evidence of bacterial changes. The study of adaptive mutations is important for understanding the power and the limitation of mutations for change in bacterial species. This may assist creation models of speciation, adaptation, and pathogenesis of bacteria in the post-Fall and post-Flood world.

Definition of Adaptive Mutation

Hall (1998b) summarizes adaptive mutations well when he writes:

Adaptive mutations differ from growth-dependent mutations in two key respects. First, adaptive mutations occur in nondividing or slowly dividing cells which are under selection for a particular phenotype, whereas growth-dependent mutations occur in dividing cells that are not under strong selection. Second, adaptive mutations produce only those phenotypes which allow the cells to grow, whereas growth-dependent mutations occur randomly with respect to their effects on fitness (p. 2862).

Adaptive mutations are those that allow bacteria to survive preferentially under non-lethal selection. These mutations were once called “directed” as they were thought to occur only in genes that allowed for the metabolism of the metabolite being used in the selection. However, adaptive is a better description as mutations in genes not under selection have also been found (Torkelson et al., 1997). The bacteria used for studies of adaptive mutation are typically deficient for the ability to metabolize a particular substance, like lactose.

Initially, metabolically deficient bacteria (auxotrophs) are grown on minimal media supplemented with the metabolite (that the bacteria cannot metabolize) as the sole energy source. Most of the bacteria do not grow on this media. Those that grow shortly after selection begins (usually within two days) most likely have mutations that allowed them to utilize the metabolite before they were plated on the minimal media. These are growth dependent mutations that occurred during the normal process of growth of the bacteria on complete media *before* placement on minimal media. However, 95% of the mutations that occur once the bacteria have been cultivated for a week on minimal media are adaptive mutations that occurred *after* being placed on the minimal media (Foster, 1999). This situation of starvation closely mimics reality for those bacteria living in nutrient poor environments.

In some cases adaptive mutations in bacteria are simple reversions of the auxotroph back to the prototroph. For example, one Lac⁻ strain of *E. coli* contains a +1 frameshift in the *lac* operon (on the F' plasmid) which inactivates it. Adaptive mutations in this strain are a reversion of the frameshift such that the *lac* operon is now active (Cairns & Foster, 1991). Hall's research involved using an *E. coli* Lac⁻ strain (W4680) in which there is a deletion of approximately 1/3 of the *lacZ* gene (Hall, 1978a, 1978b). This cannot be corrected through a simple reversion in the *lac* operon, thus adaptive mutations were not seen in the *lac* operon but in the related *ebg* operon.

Lac and ebg Operons

The *lac* operon of *E. coli* is subject to negative regulation. It consists of several genes designed to allow lactose into the cell, for the catabolism of lactose, and the regulation of the *lac* operon (Figure 1). *lacZ*, *Y*, and *A* are structural genes encoding β-galactosidase (β-gal), galactoside permease (*lac* permease), and thiogalactoside transacetylase, respectively. *lac* β-gal is responsible for the catabolism of lactose and the isomerization of lactose to allolactose needed to induce the *lac* operon. *Lac* permease is a membrane

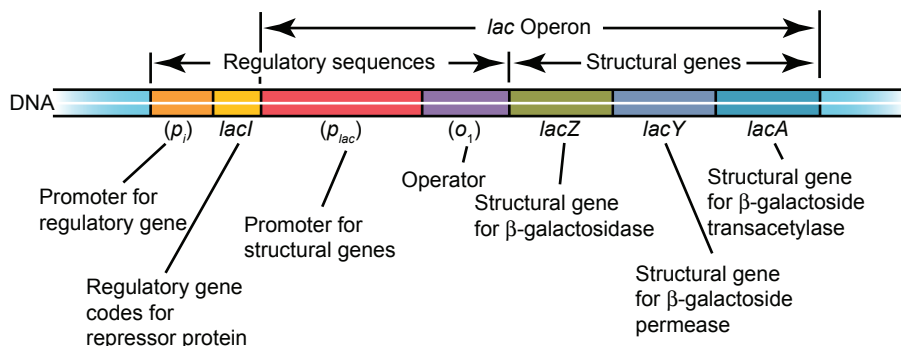

Figure 1. *Lac* operon. Additional operator region O_2 is located upstream of O_1 and operator region O_3 is located within *lacZ*.

Figure 2. Proposed structure of *ebg* operon.

bound protein that transports lactose into the cell. Thiogalactoside transacetylase is encoded by the *lac* operon, but its function is not known. *lacI* encodes the *lac* repressor. A promoter and operator sequence are located between *lacI* and genes *lacZ*, *Y*, and *A*. When lactose is absent, the repressor binds to the operator and greatly reduces the rate of transcription of *lacZ*, *Y*, and *A*. This is an energy conservation mechanism since *E. coli* preferentially catabolizes glucose. In the absence of glucose and presence of lactose, lactose is isomerized to allolactose by *lac* β-gal. Allolactose binds to the *lac* repressor which prevents it from binding to the operator and transcription of the *lac* operon structural genes greatly increases. Isopropylthiogalactoside (IPTG) is a powerful, nonmetabolizable inducer of the *lac* operon commonly used in experimental studies.

The *ebg* operon of *E. coli* (Figure 2) is also subject to negative regulation (Hall & Hartl, 1975) but the natural substrate of this operon is unknown (Hall, 1999a). *ebgA*, *B*, and *C* are structural genes encoding the α subunit of the *ebg* β-galactosidase (*ebg* β-gal), a protein of unknown function but structurally similar to transport proteins, and the β subunit of *ebg* β-galactosidase, respectively (Hall, 1999a). *ebgR* encodes the *ebg* repressor (Hall, 1999a). The promoter and operator sequences have not been determined experimentally but have been predicted from the DNA sequence (Hall, Betts, & Wootton, 1989). *ebg* β-gal can catabolize lactose (better than any other β-galactosidase sugar) but not sufficiently to allow growth on lactose even when approximately 5% of the soluble protein in the cell is *ebg* β-gal (due to a defective repressor) (Hall, 1999a). Mutations in both *ebgA* and *ebgR* are required for lactose utilization (Hall & Clarke, 1977).

lacZ and *ebgA* sequences show a 50% DNA homology and a 33% amino acid homology (Stokes, Betts, & Hall, 1985). *lacI* and *ebgR* sequences show a 44% DNA homology and 25% amino acid homology (Stokes & Hall, 1985). Stokes and Hall have hypothesized that rather than gene duplication these two operons may have been the result of whole

Class IV was discovered to have an activity not found in Class I and Class II. Class IV has transgalactosylation activity that allows it to convert lactose to allolactose (Rolseth, Fried, & Hall, 1980). Thus, Class IV does not require IPTG as an inducer of *lac* permease, and can now regulate the *lac* operon itself (Rolseth, Fried, & Hall, 1980). It is the only class of *ebg* mutants that could survive *in vivo*.

Classification of *ebgR* Mutations

Hall discovered that *ebgR* mutations are more wide ranging than those of *ebgA* (for a complete list of mutations see Hall, 1999b). All of the selections were performed using *E. coli* K12 strains (W4680) possessing the *lacZ* deletion and were also mutant for *ebgA* (*ebgA51⁺*, Class II mutant) (Hall, 1978a). The media was supplemented with IPTG which is necessary to induce the synthesis of *lac* permease necessary for translocation of lactose into the cell (Hall, 1978a). The *ebgA51⁺* operon is under the control of wild-type *ebgR* and is inducible by lactose and lactulose but not sufficiently to allow survival on either sugar (Hall & Clarke, 1977). Selection using lactulose recovered strains that had mutations in *ebgR* (designated with an "L" for lactulose induction) that allowed growth via induction by lactulose as well as several other β -galactosidases (Hall, 1978a). This seems to indicate an altering of the specificity of *ebgR* (Hall, Betts, & Wooton, 1989). The fold induction increase by these sugars was 10 to 90 fold greater than their induction of the wild-type *ebgR* (Hall, 1978a). Mutations in the predicted sugar binding region were revealed through sequence analysis of several of the *ebgR⁺L* mutants (Hall, Betts, & Wooton, 1989). Interestingly, all of the *ebgR⁺L* mutations were inducible and not constitutive (Hall, 1978a). This suggests a strong selection for non-constitutive mutations in *ebgR* in addition to *ebgA*.

Later studies revealed that the majority of mutations in *ebgR* are mediated by insertion elements IS1 and IS30 (Hall, 1999b). Interestingly, only about 4% of *lacI* mutations are mediated by insertion elements (Hall, 1999b).

Natural Function of the *ebg* Operon

Although the natural substrate of *ebg* β -gal is unknown, it is important to speculate on its natural role. A search of the NCBI protein database shows that several species of *Shigella* (a close relative of *E. coli*) possess the genes for *ebgR* and the α subunit of *ebgA*. *Shigella* poorly utilizes lactose due to the absence of the *lac* operon (Stoebel, 2004). It is unknown for both *E. coli* and *Shigella* if the *ebg* operon is essential. It is also unknown if *Shigella* would acquire similar mutations in the *ebg* operon if it were placed under similar conditions that produced the adaptive mutations in the *E. coli* *ebg* operon.

It is impossible to know if the adaptive mutations at 92 and/or 977 in *ebgA* affect its normal function. The function of the *ebg* operon may not be essential or may be replaced by a functionally redundant system since these mutants grow well under laboratory conditions. However, since these mutations occur in the active site of *ebgA* it is likely to affect its function by either causing *ebgA* to lose specificity or change specificity. This is commonly observed with mutations in enzymes (Herring et al., 2006).

Pseudogene

One possibility is that *ebgA* is a pseudogene. Pseudogenes were once thought to be rare in bacteria, however, recent work indicates they are common; encompassing 1–5% of individual bacterial genomes (Liu, Harrison, Kunin, & Gerstein, 2004). Just as in eukaryotes, prokaryotic pseudogenes may arise from duplications of native genes or mutations in native single copy genes (Liu et al., 2004). Unique to prokaryotes is the possibility that pseudogenes arise from failed horizontal gene transfer events (Liu et al., 2004). Pseudogenes were once thought to be defunct relatives of known genes. While this may be the case for some, recent studies have shown some pseudogenes can be functional in gene regulation (Balakirev & Ayala, 2003; Zheng et al., 2007). Hall believes that the high level of sequence conservation between *ebg* β -gal and other *lac* β -gals diminishes the possibility that *ebgA* is a pseudogene (Hall, 1999a). As papers regarding the functionality of pseudogenes have only recently been published (last five years), it is possible that *ebgA* is a pseudogene with an unknown regulatory function.

Backup system

Another possibility is that the *ebg* operon represents a functionally redundant backup system for the *lac* operon. In many species from bacteria to humans, functional redundancy exists between certain genes. Functional redundancy has been a deterrent in minimal genome determination for microorganisms as a gene may not be classified as essential due to the presence of two genes that can perform the same function—delete one and the other still performs the necessary function (Pál, Papp, Lercher, Csermely, Oliver, & Hurst, 2006). Additionally, even if a microorganism can survive with only one copy of genes for a particular function, it may not be as robust to mutations since it is now lacking a backup copy. Interestingly it has been shown that these backup systems are regulated in such a way that if the essential gene becomes mutated or inactivated the backup gene (responsive gene) becomes activated (Kafri, Levy, & Pilpel, 2006). For example, in the yeast *Saccharomyces cerevisiae*, *Fks1*

and *Fks2* are involved in cell wall formation and are functionally redundant (García-Rodríguez, Trilla, Castro, Valdivieso, Durán, & Roncero, 2000). When *Fks1* becomes inactivated by mutation, *Fks2* becomes up-regulated (García-Rodríguez et al., 2000). Kafri, Levy, and Pilpel state,

We thus challenge the view that such redundancies are simply leftovers of ancient duplications and suggest they are an additional component to the sophisticated machinery of cellular regulation. In this respect, we suggest that compensation for gene loss is merely a side effect of sophisticated design principles using functional redundancy (p. 11653).

Although wild-type *ebg* β -gal is not functionally redundant to *lac* β -gal, it is possible that the regulation of backup genes may involve activating mutation mechanisms (such as those leading to the hypermutable state in bacteria- see appendix). This would result in mutations in backup genes that lead to proteins that can perform the same function as the proteins from essential genes. Possibly *ebgA* serves as a backup gene for several essential genes and the most flexibility within the system is achieved by altering *ebgA* in accordance with the particular essential gene that has been inactivated.

Further support of the idea that the *ebg* operon is a backup system is implicated by the findings that adaptive mutagenesis of *ebgR* is regulated. Hall found that mutations in *phoPQ* genes decrease the number of adaptive mutations in *ebgR* by a factor of 6 (Hall, 1998b). He also found mutations in several other genes that increase or decrease the adaptive mutation rate of *ebgR* but these were not further investigated (Hall, 1998b). Interestingly, the disruptions in *phoPQ* did not affect the adaptive mutation rate of other operons such as *trp* and *bgl*, thus, *phoPQ* appears to be specific for affecting adaptive mutagenesis of *ebgR* (Hall, 1998b). In addition, disruptions in *phoPQ* did not affect the rate of growth-dependent mutations in *ebgR*, only the adaptive mutation rate (Hall, 1998b). *PhoPQ* responds to adverse environmental conditions (such as nutrient deprivation) by directly or indirectly up-regulating the expression of many genes (Groisman, Hefron, & Solomon, 1992). This lends further support to the idea that when *lacZ* is mutated and lactose is the only carbon source, mechanisms (such as *phoPQ*) are initiated. This leads to mutations in the putative Ebg back up system that result in a functional *ebg* β -gal that can utilize lactose and allow survival and growth of the bacteria.

Mutations in the Ebg System are not an Example of Evolution

Evolution (primarily neo-Darwinism) is currently the dominant paradigm in origin science. Within this context, scientists have diligently worked to assign

an evolutionary role for adaptive mutations. This is exemplified by the title from one of Hall's papers, "Experimental evolution of Ebg enzyme provides clues about the evolution of catalysis and to evolutionary potential" (Hall, 1999a).

However, the most widely accepted definition of evolution is simply "change of gene frequency over time." This vanilla definition neither describes the types of changes nor the extent of these changes. As such, it offers little insight into either the mechanism or the function of evolution. It also does little to distinguish itself from a creation model of origins.

A more appropriate definition (and explanation) of evolution is "descent from a common ancestor" or "common descent." This infers that all contemporary life is descended from a common ancestor(s) billions of years ago through the progressive modification of their DNA. However, papers dealing with the Ebg system ultimately provided little evidence in support of "common descent." Rather, the observations of these studies were simply the adaptive aspects of bacteria, as the term adaptive mutations implies. Bacteria, facing adverse environmental conditions, activate mechanisms to increase the rate of mutation in the attempt to generate a variety of mutations, one class of which may give the population the ability to survive and grow under a given adverse condition (see Anderson, 2003 for a more complete description of this characteristic).

Not surprisingly, the field of adaptive mutagenesis was initially met with very strong resistance. Early findings by Hall and Foster/Cairns seemed to indicate that the only mutations that were occurring were those specific for dealing with the selective pressure that the bacteria were under (Cairns, Overbaugh, & Miller, 1988; Hall, 1990). This would seem to contradict the randomness of mutations (or a mutation rate independent of the environment) required by Neo-Darwinian philosophy (Mayr, 1982). Torkelson et al. (1997) comments,

Adaptive mutation provoked controversy about whether mutagenesis mechanisms exist that direct mutation preferentially to a selected gene, in a Lamarckian manner. The unorthodoxy of this suggestion led many to argue that adaptive mutations must not exist. (p. 3303).

As mentioned, adaptive mutations were originally called directed mutations because they seemed to be specific in relation to the selective pressure. Stahl dubbed them, "a unicorn in the garden" (Stahl, 1988). Lenski, Slatkin, and Ayala (1989) state,

If the hypothesis of directed mutation is, indeed correct, it has onerous implications for bacterial genetics and, in particular, for the use of bacterial populations as model systems for the study of evolutionary processes. (p. 2775).

Several recent papers proposing alternate “random” processes have been countered by additional research supporting a more “directed” attribute of the adaptive mutation (see Anderson & Purdom, 2008). If, indeed, adaptive mutations are “directed” by environmental conditions, a glaring problem would be posed to any phylogenetic reconstruction that is dependent on DNA sequence differences. Hall (1988) comments,

If the probabilities of particular mutations are subject to environmental modulation, then the number of observed differences between two sequences may be completely unrelated to the time since they diverged. (p. 896).

Thus, environmental pressures are speeding up changes in the DNA, the mutation rate has not been constant throughout time, and DNA sequence differences are not an accurate “clock.”

“A true acid test”

As mentioned previously, Kenneth Miller has used Hall's work on the *ebg* operon as evidence that evolution can give rise to irreducibly complex systems (Miller, 1999). Miller believes that what Hall has observed is the “evolution” of a 3-part system necessary for lactose utilization. The three parts include a lactose-sensitive *ebg* repressor, *ebg* β -galactosidase, and the ability of *ebg* β -gal to form allolactose which induces *lac* permease. He states, “Unless all three are in place, the system does not function, which is, of course, the key element of an irreducibly complex system.” (Miller, n.d.).

Once again, it is a matter of definition. How is Dr. Miller defining evolution? Adaptive mutagenesis of the Ebg system is not creating a new system, nor does it even impart *E. coli* with a new phenotype. Instead, the mutations, combined with selection, work on pre-existing genetic material. The wild-type *ebg* β -gal already possessed the ability to catabolize lactose (Hall, 1999a). The mutations merely restored the Lac⁺ phenotype that the mutant strain of *E. coli* had previously lost by a deletion of *lacZ*. In addition, mutations at 92 and/or 977 in *ebgA* simply allow the *ebg* β -gal system to utilize lactose better. Although Class IV *ebgA* mutants (mutations at 92 and 977) can isomerize lactose to allolactose to induce *lac* permease, the Ebg system did not “evolve” the ability to transport lactose into the cell. The system is dependent on the presence of the *lac* permease from the *lac* operon. Thus, the Ebg system for lactose utilization is incomplete. Hall's work with the Ebg system is not an example of the evolution of a new system or even a new phenotype. Rather the process of adaptive mutagenesis (through mutation and natural selection) has allowed the bacteria to make a minimal number of changes in pre-existing systems to regain a previously lost function in order to adapt to adverse environmental conditions. More time and

more beneficial mutations as achieved by adaptive mutagenesis still do not result in evolution, merely adaptation.

Another problem for adaptive mutagenesis as a mechanism for evolution is the net overall loss of functional systems. As discussed in the appendix, the proposed hypermutable state of bacteria under non-lethal selection leads to genome-wide mutations (Torkelson et al., 1997). For example, in *E. coli* Lac-cells placed under non-lethal selection with lactose generated Lac⁺ mutants that also were Xyl⁻ (inability to ferment xylose) or Mal⁻ (inability to ferment maltose) (Torkelson et al., 1997). Although these cells possessed beneficial mutations which allowed them to utilize lactose, they also possessed deleterious mutations that resulted in the loss of the ability to utilize xylose or maltose. Hall also found auxotrophic mutations among Trp⁺ revertants (Hall, 1990). It is not known if the mutations at 92 and 977 in *ebgA* affect the natural function of the Ebg system since its natural function is unknown. It is likely that these mutations do affect the natural function of *ebg* β -gal since they occur in the proposed active site. Mutations in enzymes typically alter their substrate specificity or interfere with their ability to interact with their natural substrate (Herring et al., 2006).

Hall, although not skeptical of evolution in general, does seem to conclude that his work on the Ebg system is not reflective of the experimental test or laboratory verification of evolution that Miller suggests. In a recent paper he recounted the history of his research on the Ebg system. Hall (2003) writes,

As a fresh young postdoc in 1972, I was pretty disdainful of evolutionary biology, dismissing it as just-so stories backed up by internally consistent, but experimentally untestable hypotheses (p. 143).

Underlying all of those questions was the big question: what did we have to know in order to predict both the evolutionary potential of an organism for a new gene function and the evolutionary potential of any particular ancestral gene? (p. 144).

Well, we pretty much lost sight of that question over the years of studying Ebg. We had started out wanting to be able to predict evolution but ended up, much like classical evolutionists, simply explaining what we had seen. Sure we had watched the events occur in the laboratory, but no effort to predict outcomes in advance had been attempted (pp. 154–155).

Of all living organisms, bacteria should be the perfect model for experimentally testing and verifying evolutionary predictions. Their quick generation time and large population size make it possible for laboratory observation of what have occurred over “millions of years” in nature (Lenski & Travisano, 1994). If mutation and natural selection can result in the net gain of functional systems, then

this should be observable using bacteria in the lab. However, as Hall indicated, all he was able to offer was an explanation consistent with what he observed. He was not able to make predictions about how the organism would evolve. Bacteria (a subpopulation) when placed under adverse environmental conditions enter a hypermutable state that generates multiple mutations (see appendix). Some of these mutations are beneficial and some are deleterious. Selection favors bacteria that contain mutations that restore previously lost functions that will enhance survival under the current selective pressure. The same bacteria also have mutations that are not specific to the selective pressure and have resulted in the loss of other functions. Rather than being evidence for evolution which requires a net gain of new systems with new functions, this is clear evidence for an amazing phenomenon using pre-existing systems and pre-existing functions that allows for adaptation (with no overall net gain).

How applicable are Hall's experiments to natural settings?

Although the mutations in the *ebg* operon have been observed to occur in a laboratory setting, could they also occur in a natural setting? One of our major challenges, also a concern of Behe (2000) concerning Hall's work is the amount of "intelligent intervention" that had to occur to obtain a functional, regulated *ebg* operon that could utilize lactose. The following provides a summary of these challenges.

Use of IPTG

IPTG (isopropyl-beta-D-thiogalactopyranoside) is a synthetic analog of allolactose and induces the *lac* operon. IPTG was always present in his experiments (except where noted otherwise) to induce the production of *lac* permease needed to transport lactose into the cell (Hall, 1978b). Since the *ebg* operon does not contain a gene for a lactose transporter, induction of the *lac* operon is still necessary. If IPTG is absent, lactose is not transported into the cell and subsequent mutations in *ebgA* and *ebgR* would not be positively selected.

Sugars used are not natural

Some of the sugars used for the selection schemes to obtain the different classes of *ebg* mutations are also not natural. Lactulose and galactosyl- β -D-arabinose are not found in nature and lactobionate is rare in nature (Hall, 2003). The Class IV mutants (that can utilize lactose and form allolactose to regulate the *lac* operon) are only found after selection with either lactulose (Hall, 1978b) or galactosyl-D-arabinose (Hall & Zurel, 1980). Therefore, it is hard to conceive how the *ebgA* mutations would have occurred naturally.

Double *ebgA* mutants cannot be obtained in a single step

Class IV mutants containing both Class I (at 92) and Class II (at 977) mutations were never obtained in one step (Hall, 1978b). Class IV can be obtained either by selection of Class I with lactulose (Hall, 1978b) or selection of Class II with galactosyl- β -D-arabinose (Hall & Zurel, 1980). This is relevant as Class IV mutants are the only ones able to isomerize allolactose from lactose (Rolseth et al., 1980). A Class IV mutant obtained in one step would be necessary in a natural setting as IPTG would not be present and allolactose is necessary to induce the expression of *lac* permease needed for lactose uptake. Single mutants such as Class I and Class II alone would not be positively selected in a natural setting as these cells are not be able to induce the expression of *lac* permease. So the single mutants would not be available for further mutation and selection to give rise to double mutants. It appears that the only way the double mutant (Class IV) can be obtained is through an extremely artificial selection scheme involving the presence of a synthetic inducer and unnatural sugars.

Triple *ebg* mutants cannot be obtained in a single step

A completely functional, regulated *ebg* operon that can utilize lactose requires three mutations: one in *ebgR* and two in *ebgA*. The *ebgR* mutation could be constitutive, but preferably it would be one that allows regulation by lactose so that *ebg* β -gal is only produced in the presence of lactose. This allows better economy and efficiency by the cell. The two mutations in *ebgA* (Class IV mutant) allow the cell to utilize lactose and form allolactose, which induces the expression of *lac* permease. However, all the selection schemes for *ebgR* or *ebgA* mutations always began with cells that were already mutant for one or the other. The *ebgA* mutations were obtained using cells that already had a constitutive *ebgR* mutation (Hall, 1978b). The *ebgR* mutations were obtained using cells that already had mutations in *ebgA* that allowed it to utilize lactose and lactulose (Hall, 1978a). Thus, no individual mutations in either *ebgA* or *ebgR* would be selected for. Mutations in *ebgA* without mutations in *ebgR* would not be selected for because *ebg* β -gal would not be produced. Mutations in *ebgR* without mutations in *ebgA* would not be selected for because *ebg* β -gal would not be able to utilize lactose. Roth, Kugelberg, Reams, Kofoid, and Andersson (2006) has suggested a possible sequential selection scheme with the *ebgR* mutations occurring first (as they are more likely), giving the cell some survival advantage. This is followed by the less frequent mutations in *ebgA*. However, it is difficult to understand why the individual mutations in either *ebgR* or *ebgA* would be positively selected for individually.

Roth et al. (2006) has suggested that the frequency of either the 92 or 977 mutation in *ebgA* is 10^{-9} (thus it would follow that the combined mutation frequency for both of these mutations in *ebgA* is 10^{-18}). The suggested frequency of a mutation occurring in *ebgR* is 10^{-6} (Roth et al., 2006). (These frequencies are based on the spontaneous mutation rate in growing cells not under starvation conditions which may or may not be applicable to nondividing or slowly growing cells under starvation conditions.) Thus, the combined mutation frequency of all three mutations occurring in a single strain would be 10^{-24} . This makes it very improbable that all three mutations would occur by chance in a single bacterial cell in a natural setting. While it is possible to obtain strains with all three mutations, this has only been observed in a laboratory setting using an “intelligent” selection scheme.

More contrived schemes for evolving lactose utilization

In a more recent paper, Hall (2003) presents new work that he has initiated to predict evolutionary potential by “re-evolving” lactose utilization in an *E. coli* strain that is *lacZ* and *ebgA*. Previous attempts of this approach have failed (Hall, 1995). This latest attempt was made using a *lacZ* and *ebgA* strain that also contained activating, constitutive mutations in the cryptic β -glucoside operons (Hall, 2003). Based on previous work with *lac* operons in *Klebsiella* (Hall, 1979), Hall had predicted that the β -glucosides would mutate and become β -galactosidases (Hall, 2001). Even if this new mutation scheme works, the cells were engineered with a specific, plausibly helpful mutation before the selection schemes began. It is not known how representative this would be of what could occur naturally.

Limited capabilities of adaptive mutation

As stated previously, the only mutations ever found by Hall in *ebgA* were changes affecting residues 92 and 977 (Hall, 1999a). Rather than showing the supposed awesome capabilities of mutation and natural selection as mechanisms for evolution this would seem to indicate that mutation and natural selection are very limited in what they can accomplish. The 92 and 977 changes are within the active site of *ebgA*, and *ebg* β -gal has known homology to other β -galactosidases (Hall, 1999a). It is difficult to fathom the number of mutations that would need to occur in an unrelated enzyme to accomplish the same goal (utilization of lactose). Riley and Anilionis (1978) state:

The gain of metabolic function by these mechanisms [adaptive mutation] relies on the presence in the genome of genetic information that is nearly adequate to the task at the time the selection condition is imposed (p. 528).

Mechanisms of this kind [generating adaptive mutations] would seem best suited to find tuning and the maintenance of a certain degree of responsiveness, but such mechanisms do not seem suited to the task of bringing about the larger kinds of evolutionary changes that must have been required in the acquisition by primitive organisms of major new metabolic capabilities that would require acquisition of entire new pathways and new forms of energy capture (p. 528).

Later work by Hall seems to have born this out as he was unable to “evolve” lactose utilization (“despite extensive efforts”) in an *E. coli* strain that was *lacZ* and *ebgA* (Hall, 1995). However, in the same article Hall (1995) states, “Obviously, given a sufficient number of substitutions, additions, and deletions, the sequence of any gene can evolve into the sequence of any other gene” (p. 516). This statement seems contradictory to his findings, and seems to be based more on a theoretical possibility, but not probable in reality.

In vitro compartmentalization studies performed using *ebgA* provide further evidence that while many mutations in genes may be possible (theory), they are not probable (reality) (Mastrobattista et al., 2005). These studies utilized a cell-free system of aqueous droplets into which a *lacZ*-, *ebgA/C* mutant library had been incorporated (Mastrobattista et al., 2005). The activity of the resultant mutant *ebg* β -gals was assessed using a fluorescent substrate (Mastrobattista et al., 2005). Many different mutations in *ebgA* (in conjunction with mutations in *ebgC*) resulted in *ebg* β -gals that had activity towards the substrate (Mastrobattista et al., 2005). These mutations were typically a combination of multiple base substitutions in *ebgA* and multiple base substitutions and/or nonsense mutations in *ebgC* (Mastrobattista et al., 2005). Interestingly, only one Class I mutant was found and no Class II mutants were found (Mastrobattista et al., 2005). While this system is extremely artificial and the activity of the *ebgA/C* mutants towards lactose is not known, it would seem to indicate that although many mutations in *ebgA/C* result in active β -gals that natural selection cannot effectively “see” them. It is plausible that some of these same mutations in *ebgA/C* occurred in the experimental conditions used by Hall. However, these mutants were not selected by natural selection.

It is possible that many of the mutations observed by Mastrobattista et al. (2005) in *ebgA/C* fall into the “no-selection zone” as hypothesized by Kimura (1979). This zone includes mutations which are nearly neutral, and although altering the genotype individually these mutations have no detectable effect on the phenotype. Since selection occurs at the phenotypic level, these mutations are essentially not “seen” (Sanford, 2005).

While a theoretical plausibility, these mutations are highly improbable.

In vivo, many more constraints exist that may limit the mutations in *ebgA* to the 92 and 977 residues. For example, the interaction of *ebgA/C* with other substrates, proteins, or regulatory molecules may be affected by many of the mutations discovered *in vitro*. The β subunit encoded by *ebgC* may play an important role in these interactions since no mutations in this gene are found in strains that survive and grow *in vivo* but many mutations including nonsense mutations are found in *ebgC in vitro*.

Hall suggests that possibly the genetic code actually imposes constraints on the changes in the resulting protein (besides the change in the “shape” of the protein) (Hall, 1995). Other amino acid replacements at 92 and 977 may allow *ebg* β -gal to function effectively; however, these changes may require two mutations versus one (Hall, 1995). The *in vitro* studies, while confined to the same genetic code, do not face the selective pressures of the *in vivo* situation. Thus, multiple mutations are more readily observed. Hall suggests,

The present study shows that, independent of that outcome [a proposed amino acid replacement other than the one found], the existing sequence of the wild-type *ebgA* gene, together with the genetic code, impose an evolutionary constraint against that particular solution under these experimental conditions (p. 516).

This further confirms the concept that while many mutations are possible, not all mutations are probable.

If the *ebg* operon is a backup system for more than just the *lac* operon, fewer changes may be preferable because nutrient conditions may change. The *ebg* operon may then need to be altered to allow for the catabolism of a substrate other than lactose. This allows the bacteria to maintain a sort of “rigid flexibility.” Transient mutator populations (such as those proposed by the hypermutable state model for adaptive mutation—see appendix) allow bacterial populations to change rapidly in a constantly fluctuating environment where adaptation is necessary for survival and growth. For bacteria this would appear to be an efficient use of energy and resources. However, as stated previously, adaptive mutations do not create the existence of new functional systems (as required by evolution) but rather allow for the remarkable utilization of current genetic material (as required by adaptation).

Adaptive mutation results in limited changes in protein function

The amino acid replacements at 92 and 977

did not result in *ebg* β -gal performing a completely new function. Wild-type *ebg* β -gal does have the ability to catabolize lactose, albeit inefficiently (Hall, 1999a) (Table 4). Thus, the mutations in *ebgA* served to enhance its ability to catabolize lactose compared to wild-type *ebgA* (Hall, (Table 4). Enhancing a previously existing function fits well within the paradigm that adaptive mutations help an organism survive stressful environments. It is not evidence that adaptive mutations play a role in evolution, which requires the gain of completely new functions.

It is a well known fact that mutations typically alter the previously existing function of a protein as has been shown in the case of many antibiotic resistance mutations (Anderson, 2005). This appears to be applicable to Hall’s work as well. For example, Class IV mutants, although able to metabolize a wider range of sugars, actually have less activity towards lactose (the only natural sugar used in these experiments) than Class I and II (Hall, 1999a) (Table 4). Additionally, Hall discovered that Class V mutants, which are Class IV mutants that can also catabolize lactobionate, do so at the cost of not being able to catabolize other sugars as well as the Class IV mutants (Hall) (Table 4). This does not even take into account the possible alteration of the natural function of *ebg* β -gal. Adaptive mutations cannot help an organism move in a vertical direction as required by evolution if the mutations consistently counteract themselves. They can only help in the horizontal direction as is necessary for adaptation to a constantly changing environment.

Adaptive mutation has no foresight

As has been stated previously, the three mutations required for the Ebg system to be independent of the need for IPTG (an artificial inducer); one in *ebgR* and two in *ebgA*. No selection scheme could produce all three mutations in a single step. In fact, any one of

Table 4. Kinetic properties of *ebgA* and *lac* β -galactosidases. Summary of the activities of the wild-type *ebgA*, *ebgA* mutants, and *lacZ* β -galactosidases with various substrates.

Enzyme	Lactose	Lactulose	Galactosyl-arabinose	Lactobionate
Wild-type <i>ebgA</i>	1.46	0.62	0.12	no detectable activity
Class I	8.2	0.16	0.43	no detectable activity
Class II	5.4	4.3	0.82	no detectable activity
Class IV	3.4	0.99	1.7	0.24
Class V	1.4	0.49	0.80	3.0
<i>lacZ</i>	150	19.6	37.5	not determined

*Data from Hall (1999a)

*K^{cat}: moles of substrate hydrolyzed per second per mole of enzyme at 37°C.

the mutations would likely be selected against. The bacteria would not keep a single, useless, mutation with the anticipation that future mutations will allow this initial mutation to become beneficial. These mechanisms have no such foresight. This is also true of evolution—it could not keep a single mutation that serves no useful function with the hope that further mutations will allow the initial mutation to provide some benefit in a given environment. Evolution also has no foresight.

Creation Model for Understanding and Utilizing Adaptive Mutation **Classification of bacterial kinds**

Adaptive mutations in bacteria are a testament to the grace of God in supplying for His creation. After the Fall and Flood, the conditions of the world changed dramatically. Many organisms did not survive. However, bacteria designed with the ability to adapt to ever changing environments most likely coped well with these changes. One of these mechanisms, adaptive mutation and in particular the hypermutable state model (see appendix), has been described in this work. Other models, such as the amplification model and amplification-mutagenesis model, have also been suggested to lead to adaptive mutation (Hendrickson, Slechta, Bergthorsson, Andersson, & Roth, 2002; Stumpf, Poteete, & Foster, 2007). In addition, depending on the starvation condition and the original genotype of the organism, the mechanism employed to adapt may differ. For example, during amino acid starvation *E. coli* derepresses the biosynthesis operon for the specific limited amino acid. Wright, Longacre, and Reimers (1999) found that in *leuB*- *E. coli* the *leu* operon is de-repressed and *E. coli* can revert to *leuB*+ by a starvation-induced transcription model. This leads to increased transcription of only the *leu* operon and hypermutation specifically in the *leu* operon (Wright, Longacre, & Reimers, 1999). This is different from the hypermutable state model proposed by Hall for the *Ebg* system where genome wide hypermutation is observed during lactose starvation (Hall, 1990; Torkelson et al., 1997; and appendix). Determining the adaptive mechanisms used by the spectra of bacterial species may assist in the process of classification of bacterial kinds. To date, no attempt has been made to classify bacteria into original created kinds.

Pathogenesis

It is likely that adaptive mutation was not needed until after the Fall, when bacteria began dealing with an imperfect environment. Mutations in bacteria that lead to pathogenicity would not have occurred until after the Fall. One possibility is that pathogenicity is a detrimental (to other organisms) side effect of

adaptive mutation. Pathogenicity may not be the result of completely random mutations. Joseph Francis (2008) suggests,

From a creation view, it appears then, that the origin of microbial based disease has at least two primary causes (1) post-Fall genetic alteration of the original good microbe and/or (2) post-Fall displacement or movement of the microbe from the site where it performed its beneficial function.

Adaptive mutations (“alteration[s]”) while performing a beneficial function in a given environment may have pathogenic effects should the microbe move or be moved to a different location (“displacement”). This phenomenon of displacement is observed when bacteria on the skin (which have no pathogenic effect) enter the blood stream through a break in the skin (such as during surgery) and exert a pathogenic effect. As more pathogenic bacterial genomes are sequenced, it will be important to understand the function of the proposed pathogenic genes in the metabolic activities of the bacteria.

Limits of genetic changes

Neo-Darwinism proposes that mutation and natural selection make completely random changes in organisms that over time lead to a microbe becoming a microbiologist. Adaptive mutation throws a wrench into the evolution machine. Wright, Longacre, & Reimers (1999) state,

The current paradigm of neo-Darwinism as formulated by Weisman rejects any influence of the environment on the direction of variation. However, prolonged nutritional stress results in a general increase in mutations rates; the introduction of environmental effects on specific mutations rates is a reasonable extension of what is known... (p. 5094).

The body of evidence seems to indicate that adaptive mutation is a real phenomenon (Stumpf, Poteete, & Foster, 2007). For creationists, adaptive mutation fits well within the paradigm of God's design and providence for His creation. God foreknew that the Fall and Flood would occur and that bacteria would need the ability to adapt to altered environments. Bacteria have been designed with great genetic diversity that sometimes is only accessible through genetic alterations such as adaptive mutations. Thus, the *ebg* operon may be part of a complex backup system for the *lac* operon in *E. coli*.

Bacteria are great economists and change according to supply and demand. Random changes that do not help them deal with their environment will likely be lost quickly. Adaptive mutations provide an even greater genetic flexibility and response. A logical assumption, therefore, is that bacteria were created with an inherent ability for adapting to rapid and dramatic environmental changes. As such,

adaptive mutation may be the reigning mechanism for change in bacteria, especially considering they typically reside in nutrient poor environments. Adaptive mutation alters current functional systems in bacteria; it does not serve to add new functional systems necessary for evolution. Thus it is an error to assume such mutations can produce large genetic changes in the bacterium (such as those necessary for “common descent”). Certainly, adaptive mutations fit well with a creation model that allows for change within a created kind (or baramin), but they do not appropriately fit with change between created kinds.

Conclusion

Rather than being an example of “evolution in action,” adaptive mutation is an awesome witness to God’s design of bacteria. Hall’s discovery of adaptive mutations in the *Ebg* system do not pass Miller’s (1999) “true acid test” for the evolution of a new biochemical pathway. Evolution requires random mutations, natural selection, and time to bring about new functional systems. Mutations in the *ebg* operon do not serve to add a new functional system to the bacteria. Rather they enhance a previously existing function of *ebg* β -gal, that of catabolizing lactose. Adaptive mutation leads to the alteration of current genetic material to allow the bacteria to adapt to adverse environmental conditions. The terms evolution and adaptation should not be equivocated. Adaptive mutations are not evidence for evolution (defined as descent with modification) as the bacteria remain bacteria with the gain and loss of specific functions. Although the mutations in the *ebg* operon were obtained through contrived methods that may not occur naturally, Hall’s work has helped to show what bacteria are potentially capable of and that adaptive mutation is a real phenomenon.

Acknowledgments

We would also like to thank Barry Hall for communications with us that provided an inside look at his research.

Appendix

Possible Mechanisms for Generating Adaptive Mutations

The mechanisms for generating adaptive mutations are still being debated. It appears there is more than one mechanism to accomplish the same goal, and the mechanism(s) employed depends on the species and the starvation conditions. Tenaillon, Taddei, Radman, and Matic (2001) suggest a type of second-order selection applies here:

...while selecting for adaptive mutations [first-order selection], evolution [sic] indirectly selects for a system that creates these adaptive mutations, thus allowing second-order selection to regulate the mutational process. This results in at least transient enrichment for cells exhibiting increased rates of genetic change (p. 11).

Under starvation conditions, a stress response is initiated in bacteria (Figure 3). The first step in the stress response is the production of the sigma factor, σ^s (encoded by the *rpoS* gene) (Zambrano & Kolter, 1996). σ^s binds to RNA polymerase and affects which promoters are recognized and transcribed and also plays a role in translation efficiency and protein stability (Zambrano & Kolter, 1996). σ^s is also believed to play a role in making double-strand-break repair error prone in multiple ways (Rosenberg & Hastings, 2004). There are several proposed models to explain pathways leading to adaptive changes following *rpoS* induction. The pathway choice may be dependent on the bacterial species, starvation conditions, and/or initial mutations in the bacterial population being studied.

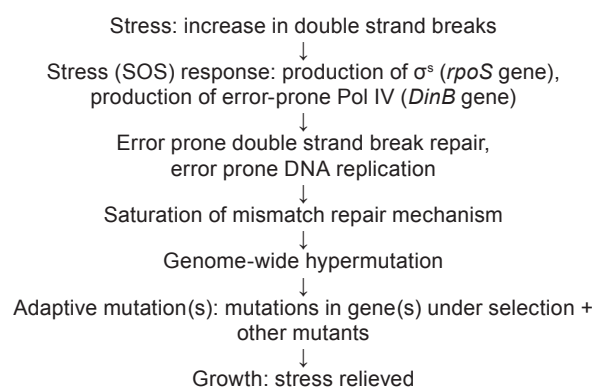

Figure 3. Adaptive mutation-hypermutable state model. This flow diagram illustrates the hypothesized hypermutable state model of adaptive mutation.

Hypermutation model

The hypermutation model (also called hypermutable state model) is the most applicable to Hall's research on the *ebg* operon (Figure 3). Hall (1990) was the first to suggest the idea of hypermutation in bacterial colonies undergoing starvation.

Consider that, at any instant during periods of prolonged starvation, some fraction of the cells in a colony enter into a hypermutable state in which extensive DNA damage and resulting error-prone repair synthesis occur, while the remaining cells in the colony remain essentially immutable. When cells are in the hypermutable state, mutations might occur at many sites in the same cell. If one of those mutations provided a solution to the current problem of blocked growth ... then the cell could exit the hypermutable state and be recovered (as a mutant) (pp. 14–15).

It appears that genome wide hypermutation occurs in a subpopulation of the cells being subjected to starvation/selection. These cells in addition to adaptive mutations which allow them to grow also have mutations in genes not under selection (Torkelson et al., 1997). Other studies have shown that most of these cells are in a transient state of hypermutation versus a heritable one (Torkelson et al., 1997). The advantage of this would be that once a mutation occurs that allows growth in the given conditions, further mutations and subsequent damage to the genome would not occur due to exiting the hypermutable state. The state of hypermutation can be achieved through multiple mechanisms that are all likely initiated by σ^s . All of these mechanisms are related to DNA replication, proofreading and repair (Bridges, 2001). Although it seems counterintuitive that nondividing or slowly dividing cells under starvation would be synthesizing much DNA, there is evidence that DNA synthesis occurs at 0.5%–5% per genome per day (Bridges, 2001).

Stress is believed to cause double stranded breaks

(DSB) in DNA. DSBs activate the SOS response in bacteria. This induces the expression of Pol IV (encoded by the gene *DinB*) (McKenzie & Rosenberg, 2001). σ^s also increases the expression of *DinB* (Rosenberg & Hastings, 2004). Pol IV is an error-prone polymerase that causes frameshifts and substitutions during DNA replication (McKenzie & Rosenberg, 2001). The large number of mutations generated by Pol IV DNA synthesis effectively saturates the mismatch repair system leading to a certain number of mutations escaping DNA repair and thus, genome wide hypermutation (Rosenberg & Hastings, 2004). Once the adaptive mutation(s) has occurred growth begins and the stress response ceases.

In the case of Hall's work on the *ebg* operon, mutations in both *ebgR* and *ebgA* would need to occur before exiting the hypermutable state. Mutations in *ebgR* are fairly common (around 10^{-6} —as many mutations will disable the repressor) whereas mutations in *ebgA* are much rarer (around 10^{-18} —two changes at positions 92 and 977 are necessary to allow utilization of lactose) (Roth et al., 2006). (These frequencies are based off the spontaneous mutation

rate in growing cells not under starvation conditions.) Some have questioned if the mutation rate necessary for a workable hypermutation model is unrealistic (Roth, Kofoid, Roth, Berg, Seger, & Andersson, 2003). Mutation rates for growing cells may not be applicable to starved cells. Mechanisms for generating mutations in growing cells are different than those in starved cells evidenced by the ability of certain mutant strains to revert when growing but not under prolonged selection (Hall, 1998a).

The specificity of the mutations seen in *ebgA* appears to be the result of selective capture vs. selective generation. Although selective generation has not been completely ruled out, it seems unlikely that a mechanism exists which specifically targets genes under selection (Hall, 1998a). Rather than selection generating mutations, selection is capturing mutations that give cells a growth advantage under the selection conditions (Hall, 1998a). While mutations in genes not under selection occur, they are likely to be "hitchhikers" resulting from genome wide hypermutation.
